

**METHOD AND APPARATUS FOR TRANSMITTING PACKETS WITHIN A  
SYMMETRIC MULTIPROCESSOR SYSTEM**

5

**BACKGROUND OF THE INVENTION**

**1. Technical Field**

The present invention relates to data processing systems in general, and in particular to symmetric multiprocessor systems. Still more particularly, the present invention relates to a method and apparatus for transmitting packets among processing nodes within a symmetric multiprocessor system.

**2. Description of the Prior Art**

It is well-known in the computer arts that greater processing performance can be achieved by harnessing the processing power of multiple individual processors in tandem. Multiprocessor computer systems can be designed with a number of different architectures, of which one may be better suited for a particular application over the others, depending upon the intended design, system performance requirements, and software environment. Known multiprocessor architectures include, for example, symmetric multiprocessor (SMP) system architecture and non-uniform memory access (NUMA) system architecture.

In an SMP data processing system, all of the processing units are generally identical; that is, they all have the same architecture and utilize a common set or subset of instructions and protocols to operate. Typically, each processing unit includes a processor core having at least one execution unit for carrying out program instructions. In addition,

10

15

20

25

each processing unit may include at least one level of caches, commonly referred to as level one (L1) caches, which are typically implemented with high-speed memories. Similarly, a second level of caches, commonly referred to as level two (L2) caches, may also be included in each processing unit for supporting the L1 caches. Sometimes, a third level of caches, commonly referred to as level three (L3) caches, may also be included in each processing unit for supporting the L2 caches. Each level of caches stores a subset of the data and/or instructions contained in a system memory for low-latency accesses by various processor cores.

The present disclosure describes a method and apparatus for transmitting packets among various processing nodes within an SMP system.

## SUMMARY OF THE INVENTION

In accordance with a preferred embodiment of the present invention, a data processing system includes multiple processing nodes, with multiple agents at each node, connected to each other via an interconnect. A request transaction is initiated by a master agent in a master node to all receiving nodes. A write counter number is generated for associating with the request transaction. The master agent then waits for a combined response from the receiving nodes. After the receipt of the combined response, a data packet is sent from the master agent to an intended one of the receiving nodes according to the combined response. After the data packet has been sent, the master agent in the master node is ready to send another request transaction along with a new write counter number, without the necessity of waiting for an acknowledgement from the receiving node.

All objects, features, and advantages of the present invention will become apparent in the following detailed written description.

## BRIEF DESCRIPTION OF THE DRAWINGS

The invention itself, as well as a preferred mode of use, further objects, and advantages thereof, will best be understood by reference to the following detailed description of an illustrative embodiment when read in conjunction with the accompanying drawings, wherein:

Figure 1 is a block diagram of a multi-node data processing system, in accordance with a preferred embodiment of the present invention;

Figure 2 is a block diagram of a processor that can be utilized to implement any agent within the data processing system from Figure 1, in accordance with a preferred embodiment of the present invention;

Figure 3 is a block diagram of a communication logic block within the processor from Figure 2, in accordance with a preferred embodiment of the present invention;

Figure 4 is a state diagram of a request transaction in the data processing system from Figure 1, according to the prior art;

Figure 5a depicts an exemplary format of a request transaction transmitted via an address channel of the data processing system from Figure 1;

Figure **5b** depicts an exemplary format of a data transaction transmitted via a data channel of the data processing system from Figure 1;

Figure **5c** depicts an exemplary format of a partial combined response or combined response transmitted via a response channel of the data processing system from Figure 1; and

Figure **6** is a state diagram of a request transaction in the data processing system from Figure 1, in accordance with a preferred embodiment of the present invention.

FIG. 5b

## DETAILED DESCRIPTION OF A PREFERRED EMBODIMENT

Referring now to the drawings and in particular to Figure 1, there is depicted a block diagram of a multi-node data processing system, in accordance with a preferred embodiment of the present invention. As shown, a data processing system 10 includes a number of nodes 11a-11n, which are coupled together in a ring configuration by a segmented interconnect 20 having one segment for each of nodes 11a-11n. Each of nodes 11a-11n of data processing system 10 includes one or more agents that are coupled to interconnect 20 and are designated A0-An for node 11a, B0-Bn for node 11b, etc. Each of nodes 11a-11n also includes a respective response and flow control logic 12 for controlling the flow of transactions on interconnect 20 to its neighboring node.

Interconnect 20 is configured to operate as a high-speed, high-bandwidth bus, preferably operating at a frequency in the order of 500 Mhz or higher. Interconnect 20 includes at least one data channel 13 and several non-blocking address channels 14a-14n that are each associated with a respective one of nodes 11a-11n such that only agents within an associated one of nodes 11a-11n can issue requests on one of address channels 14a-14n. Each of address channels 14a-14n and data channel 13 is segmented, as noted above, such that each of nodes 11a-11n contains a segment of each address and data channel, and each address and data channel segment is coupled to at least two neighboring segments of the same channel. As indicated by arrows, each channel is also uni-directional, meaning that address and data transactions on interconnect 20 are only propagated between neighboring nodes in the indicated direction. In the illustrated embodiment, each segment of each of address channels 14a-14n is implemented as an address bus that conveys 32 address bits in parallel, and each segment of data channel 13 is implemented as a data bus that conveys 16 data bytes in parallel; however, it will be appreciated that individual segments of interconnect 20 can alternatively be implemented with switch-based or hybrid interconnects.

In conjunction with interconnect **20**, data processing system **10** has three sideband channels, namely, a partial combined response (PCR) channel **15**, a combined response (CR) channel **16**, and a cancel channel **17**, to respectively communicate partial combined responses, combined responses, and a cancel (or stomp) signal. As utilized herein, a PCR is defined as a cumulative response to a request of all agents within fewer than all nodes, and a CR is defined as a cumulative response to a request by all agents in all nodes. As discussed further below, agents are able to determine by reference to the PCR, CR, and cancel signal associated with a request snooped on any one of address channels **14a-14n** whether or not to service the request.

With reference now to Figure **2**, there is depicted a block diagram of a processor that can be utilized to implement any agent within data processing system **10** from Figure **1**, in accordance with a preferred embodiment of the present invention. Although each agent within data processing system **10** can be implemented with a processor, it should be understood that an agent can be any device capable of supporting the communication protocol described herein. As shown, a processor **21** includes a processing logic block **22** for processing instructions and data, a communication logic block **23** for implementing a communication protocol that governs communication on interconnect **20** (from Figure **1**), and a cache hierarchy **24** for providing local, low latency storage for instructions and data. In addition to cache hierarchy **24**, which may include, for example, level one (L1) and level two (L2) caches, the local storage of processor **21** may include an associated off-chip level three (L3) cache, such as L3 caches **19** and local memories **18**, as shown in Figure **1**. Instructions and data are preferably distributed among local memories **18** such that the aggregate of the contents of all local memories **18** forms a shared "main memory" that is accessible to any agent within data processing system **10**. Hereinafter, local memory **18** containing a storage location associated with a particular address is said to be the home local memory for that address, and the agent interposed between the home local memory and interconnect **20** is said to be the home agent for that address. As shown

in Figure 2, each home agent has a memory map **25** accessible to communication logic **23** and cache hierarchy **24** that indicates only what memory addresses are contained in the associated local memory **18**.

Referring now to Figure 3, there is illustrated a detailed block diagram of communication logic **23** from Figure 2. As illustrated, communication logic **23** includes a master control logic block **31**, a master address sequencer **32** for sourcing request (address) transactions on one of address channels **14a-14n** (from Figure 1), and a master data sequencer **33** for sourcing data transactions on data channel **13**. In order to ensure that each of address channels **14a-14n** is non-blocking, master address sequencer **32** of each agent within a given node **11** is connected to only address channel **14** associated with its node **11**. Thus, for example, master address sequencer **32** of each of agents **A0-An** is connected to only address channel **14a**, master address sequencer **32** of each of agents **B0-Bn** is connected to only address channel **14b**, and master address sequencer **32** of each of agents **N0-Nn** is connected to only address channel **14n**. To fairly allocate utilization of address channels **14a-14n** and ensure that local agents do not issue conflicting address transactions, some arbitration mechanism (e.g., round robin or time slice) should be utilized to arbitrate between agents within the same node **11**.

By contrast, master data sequencers **33** of all agents within data processing system **10** are connected to data channel **13**. Data channel **13** is non-blocking since the types of data transactions that may be conveyed by data channel **13**, which predominantly contain (1) modified data sourced from an agent other than the home agent, (2) data sourced from the home agent, and (3) modified data written back to a home local memory **18**, are statistically infrequent for applications in which the distribution of memory among local memories **18** and the distribution of processes among the agents is optimized. Of course, in implementations including only a single data channel **13**, some arbitration mechanism (e.g., round robin or time slice) should be utilized to arbitrate between agents

within the same node 11 to ensure that local agents do not issue conflicting data transactions.

Master control logic 31 also includes a write counter 39. The purpose of write counter 39 is for incrementing a write counter field within a request transaction before the request transaction is sent. Details of the write counter field will be further described *infra*.

Communication logic 23 also includes a snoop address and response sequencer 35 coupled to each of address channels 14a-14n and to sideband response channels 15 and 16, a snoop data sequencer 36 coupled to data channel 13, and snoop control logic 34 connected to snoop address and response sequencer 35 and to snoop data sequencer 36. In response to receipt of a request transaction by snoop address and response sequencer 35 or a data transaction by snoop data sequencer 36, the transaction is passed to snoop control logic 34. Snoop control logic 34 processes the transaction in accordance with the implemented communication protocol and, if a request transaction, provides a snoop response and possibly a cancel signal to its node's response and flow control logic 12. Depending upon the type of transaction received, snoop control logic 34 may initiate an update to a directory or data array of cache hierarchy 24, a write to local memory 18, or some other action. Snoop control logic 34 performs such processing of request and data transactions from a set of request queues 37 and data queues 38, respectively.

With reference now to Figure 4, there is depicted a state diagram of a request transaction in data processing system 10 (from Figure 1), according to the prior art. As shown in step 41, a request transaction is initiated by a master agent, for example, agent A0 of node 11a, mastering a read or write request transaction in an associated address channel, such as address channel 14a. The request transaction propagates sequentially from

node **11a** to node **11b** and eventually to node **11n** via address channel **14a**. After the snoop address and response sequencer **35** of each agent snoops the request transaction on address channel **14a**, as depicted in step **42**, the request transaction is forwarded to a corresponding snoop control logic, such as snoop control logic **34**, which provides to an associated response and flow control logic, such as response and flow control logic **12**, an appropriate snoop response indicating whether that agent can service (or participate in servicing) the request, as shown in step **43**. Possible snoop responses are listed in Table **I** in order of descending priority.

Table I

Snoop response	Meaning
Retry	retry transaction
Modified intervention	agent holds requested line in a modified state in cache from which data can be sourced
Shared intervention	agent holds requested line in a shared state from which data can be sourced
Shared	agent holds requested line in a shared state in cache
Home	agent is home agent of request address
Null	agent does not hold the requested line in cache and is not the home agent

The snoop responses of agents **A0-An** are then combined by response and flow control logic **12a** into a PCR output on PCR channel **15**. If during a determination of the appropriate snoop response, snoop control logic **34** of an agent within node **11a** determines that it is likely to have the highest priority snoop response of all agents within data processing system **10**, for example, Modified Intervention for a read request or Home for a write request, the agent within node **10a** asserts its cancel signal to a local

cancellation logic (not shown), which outputs a cancel signal on cancel channel 17. The cancel signal is preferably asserted on cancel channel 17.

Subsequently, node 11a sends a packet of data associated with the request to a receiving node that can service the request, as shown in step 44, and node 11a then waits for an acknowledgement (ACK) signal from the receiving node before sending another packet of data, as depicted in step 45. Each packet of data is associated with a tag. Node 11a must wait for the ACK signal from the receiving node because if node 11a sends a new packet of data right away, all nodes that are ready to receive data could see multiple uses of the same tag and cannot distinguish one packet of data from the other. However, the wait time for the ACK signal can be very long due to blocking/stalling along an interconnect, such as interconnect 20.

For example, a tag Y is used by an L2 cache for casting out data from a buffer within node A0 to node M0. Once the data is unloaded from node A0, the data can be stalled downstream on its way to node M0 due to traffic within an interconnect connected between node A0 and node M0. In the meantime, it is foreseeable that same castout buffer within node A0 may issue another address tenure with the same tag Y, but this time the data is destined for node N0. So, if the data from the first castout has not been received by node M0 before the second castout, the recipients of data on node M0 and N0 will not be able to distinguish for which node the castout data packet is intended. Thus, in the prior art, the castout buffer within node A0 is not allowed to reset and start again until an ACK signal (address-only tenure) is received by node A0 indicating that the intended destination of the castout data actually received the castout data packet. However, the wait time for the ACK signal can be very long due to blocking/stalling along the interconnect. Such problem is exacerbated in a really large processing system having many nodes due to the increasing chances of data bus stalling and the time it takes to transfer data across the processing system.

In order to avoid the wait time, a new request transaction according to the present invention is used. Referring now to Figure 5a, there is depicted a data structure of a request transaction in accordance with a preferred embodiment of the present invention. As shown, a request transaction 50 contains a master node ID field 51 for indicating the node ID of the master agent, a write counter field 52, a transaction type field 53 for indicating whether the request transaction is a read (e.g., read-only or read-with-intent-to-modify) or write request, and a request address field 54 for specifying the request address. Figure 5b depicts a similar data structure of a data transaction 55, which data transaction 55 contains a destination node ID field 56 for indicating the node ID of the destination node, a write counter field 57, and a data field 58 for containing the data.

In accordance with a preferred embodiment of the present invention, the number within write counter fields 52 and 57 are incremented by one each time a transaction request is sent. For example, the number within write counter field 52 for a first request transaction is "00," the number within write counter field 52 for a second request transaction is "01," the number within write counter field 52 for a third request transaction is "10," and the number within write counter field 52 for a fourth request transaction is "11." Then, the number within write counter field 52 for a fifth request transaction will be returned to "00."

The number of bits within write counter field 52 preferably depends upon the number of nodes and the delays in an interconnect connecting all nodes within a data processing system. For example, the number of nodes within the data processing system =  $2^n$ , where  $n$  is the number of bits within write counter field 52. Thus,  $n = \log_{10}(\text{number of nodes within said data processing system}) / \log_{10} 2$ . As such, the number of bits within write counter field 52 may be adjusted to provide an optimal performance according to the length of the interconnect, such as interconnect 20 in Figure 1. The number of bits within write counter field 52 is preferably updated by a write counter, such as write counter 39

from Figure 3.

As indicated in Figure 5c, the data structure of a response 60 includes a snoop node ID field 61 for indicating the node ID of the agent that provides the highest priority snoop response yet received, and a response field 62 for indicating the highest priority snoop response yet received.

With reference now to Figure 6, there is depicted a state diagram of a request transaction in data processing system 10 (from Figure 1), in accordance with a preferred embodiment of the present invention. A request transaction, such as a read or write, is initiated by a master agent within a first node, as shown in step 71. The address of the request transaction propagates sequentially from one node to another, as depicted in step 72. The master agent then waits for a response from one of the receiving nodes, as shown in step 73. After the receipt of a response, data is sent from the master agent to the intended receiving node that had sent the response, as depicted in step 74. Upon the completion of the data tenure, the write counter field (such as write counter field 52 from Figure 5a) of the next request transaction is incremented by one such that the next request transaction will have a higher write count than the previous request transaction. Then, the process can proceed to the next request state, repeating the sequence of Figure 6, without waiting for an ACK signal from the intended receiving node, as it is done in the prior art design.

As has been described, the present invention provides a method and apparatus for transmitting packets within a symmetric multiprocessor system. The present invention removes the tagging problem by differentiating the tag each time a given buffer is used. Therefore, the buffer can be reused right after unloading the data packet on the bus. By using the write counter of the present invention, the long wait time of re-using the same tag can be avoided, and the number of queues (such as a cast-out buffer) within a node

for storing data ready to be sent can be potentially reduced.

While the invention has been particularly shown and described with reference to a preferred embodiment, it will be understood by those skilled in the art that various changes in form and detail may be made therein without departing from the spirit and scope of the invention.

5
